Entanglement is vulnerable to degradation in a noisy sensing scenario, but surprisingly, the quantum illumination protocol has demonstrated that its advantage can survive. However, designing a measurement system that realizes this advantage is challenging since the information is hidden in the weak correlation embedded in the noise at the receiver side. Recent progress in a correlation-to-displacement conversion module provides a route towards an optimal protocol for practical microwave quantum illumination. In this work, we extend the conversion module to accommodate experimental imperfections that are ubiquitous in microwave systems. To mitigate loss, we propose amplification of the return signals. In the case of ideal amplification, the entire six-decibel error-exponent advantage in target detection error can be maintained. However, in the case of noisy amplification, this advantage is reduced to three decibels. We analyze the quantum advantage under different scenarios with a Kennedy receiver in the final measurement. In the ideal case, the performance still achieves the optimal one over a fairly large range of error probability with only on-off detection. Empowered by photon-number-resolving detectors, the performance is further improved and also analyzed in terms of receiver operating characteristic curves. Our findings pave the way for the development of practical microwave quantum illumination systems.

I. INTRODUCTION

Quantum illumination (QI) is an entanglement-assisted sensing scheme that enhances the precision and sensitivity of target detection [1–4], via entangling the signal probes with locally stored idlers. Originally developed to simply detect the presence or absence of a target, QI offers a 6-decibel improvement in error exponent due to entanglement [2]. In recent years, QI has been extended to improve target range and angle detection [5,6], demonstrating an even greater advantage over classical counterparts in the intermediate SNR region, thanks to the threshold phenomena of nonlinear parameter estimation [6].

Despite these theoretical advancements in QI, its experimental realization in the microwave domain, which is the natural scenario for its application, has faced several limitations. One of the practical challenges is the need for extensive cooling for microwave quantum limited detection, due to the high natural noise background, and the lack of developed photon-counting detection technology [7,8]. To address these issues, a solution for QI based on optical-microwave transduction has been proposed [9]. This approach utilizes an optical idler mode for noiseless storage at room temperature, and up-converts the microwave return mode to the optical domain for quantum limited joint detection of optical photons. However, the current state-of-the-art efficiency in optical-microwave transduction [10–15] falls short of what is required to sustain this transduction-based scheme in the near future.

In addition to the practical challenges, a fundamental limitation of QI is the receiver design problem. Currently, practical receivers such as the optical parametric amplifier receiver (OPAR) and the phase-conjugate receiver (PCR) can only attain half of the error exponent advantage [16]. The optimal receiver would require unit-efficiency sum-frequency generation at the single-photon level [17], which is highly challenging to realize experimentally. The problem of optimal receiver design seems to necessitate nonlinear processes and joint operations on the idler and return modes, making it difficult to implement in practice.

Previous in-principle demonstrations of QI target detection have been hindered by the aforementioned limitations. One example is an optical domain simulation, which injected noise to mimic a microwave scenario and utilized a suboptimal OPAR [18]. This approach achieved approximately 20% of the error exponent advantage. Another demonstration in the microwave domain used a digitally reconstructed PCR [19], but was unable to surpass the performance of the classical benchmark represented by an ideal coherent state source with the same mean number of photons and homodyne detection. More recently, the OPAR scheme was adapted to the microwave domain, overcoming several challenges in microwave photon processing [8] and again yielding roughly 20% of the error exponent advantage.

A recent development in the field of optimal receiver design is the correlation-to-displacement ("$C \to D$") conversion proposal, which suggests that the optimal receiver design can be achieved by heterodyne detecting the return mode separately and processing the associated conditional idler field [20]. Upon heterodyne detection of the return modes, the idler modes collapse to coherent states embedded in weak thermal noise. With the help of well-established coherent-state discrimination protocols, the $C \to D$ receiver design can attain the optimal error probability of QI [21]. This receiver design requires only programmable linear optics [22,23] and photon detection, making it more feasible for experimental realization. Additionally, it eliminates the need for mode matching between the noisy return fields at room temperature and the cooled idler fields, avoiding technical difficulties. In this study, we evaluate the feasibility of the $C \to D$ receiver design in the microwave domain. We account the lossy antenna coupling to the detection in real radar systems, by introducing loss $1 - \eta_S \leq 1$ in the return mode prior to heterodyne detection. To mitigate this loss, we suggest using parametric amplification with gain $G \geq 1$. Our results show that the full optimal 6-decibel error-exponent advantage can be retained when $G\eta_S \gg 1$ if the amplifier is quantum limited. Even if the amplifier introduces noise at room temperature, the $C \to D$ receiver still provides a 3-decibel advantage over the ideal classical system. Furthermore, we consider the case of limited detection capability in the idler modes. Instead of the complex Dolinar receiver, we consider the simpler Kennedy receiver and still observe the optimal error-exponent advantage. Finally, we compare the practical $C \to D$ receiver design with both the classical coherent-state homodyne detection and the PCR (which is more effective than the OPAR [24]).

This paper is organized as follows. Section II describes the protocol, while Sec. III recalls the basic properties and tools of QI. Section IV provides a brief review of the $C \to D$ receiver and its performance under ideal conditions. Section V discusses relevant experimental limitations in the case of microwave QI, and Sec. VI shows the

performance of the $C \to D$ module in the presence of such realistic scenarios. Section VII compares the performance of the $C \to D$ module with that of classical QI based on coherent state and homodyne detection and that of the PCR. In Sec. VIII, we consider performance enhancement if we further allow number-resolving detection. In particular, Sec. VIII B presents the Neyman-Pearson framework and receiver operating characteristic (ROC) curves. Finally, we conclude the paper in Sec. IX.

II. OVERALL PROTOCOL

As shown in Fig. 1, in a target detection scenario, the transmitter sends signals to the target, and then the receiver collects return signals and performs measurement to infer about the target's presence or absence. To benefit from entanglement, a source generates pairs of idler-signal entangled pulses. The idlers are stored locally and used to assist joint measurements with the return signals. In QI, such signal-idler entanglement provides a 6-decibel error exponent advantage, despite being destroyed by extremely lossy transmission and high noise background.

Our proposed receiver system adapts the $C \to D$ conversion approach to practical receiver operating conditions. While the idlers are cooled to $T_I \sim 10$ mK to enable quantum advantage, the returned signal part is cooled to a much higher temperature T_S for experimental convenience. Such a layout is possible as the $C \to D$ conversion module feeds only the classical heterodyne measurement results on the "warm" and noisy returned signals, to perform conditional linear optical transforms on the "cool" idler alone (indicated by the dashed line), avoiding idler contamination. Finally, photodetection is performed on the transformed idler, and a decision on the target's presence or absence is made according to the measurement result. To compensate for additional loss $1 - \eta_S$ at the receiver antenna, amplification of gain G is performed. In contrast, the loss $1 - \eta_I$ on the idler needs to be minimized and cannot be compensated. In fact, the idler pulses are not contaminated by noise, and any amplification will actually degrade the overall performance. The photodetection can be realized via coupling the microwave idler modes to transmon qubits, as demonstrated in Refs. [7,8].

III. QUANTUM ILLUMINATION FOR TARGET DETECTION

QI is a quantum based remote-sensing technique that leverages the entanglement between signal (a_S) and idler (a_I) modes. The signal mode probes a target region, while the idler one is kept at the emission station. By performing a joint measurement on the signal and idler modes, the quantum correlations of the transmitted state are exploited at the receiving station. The problem is framed as a binary decision-making task, where the two hypotheses are as follows: "target absent" (H_0) and "target present"
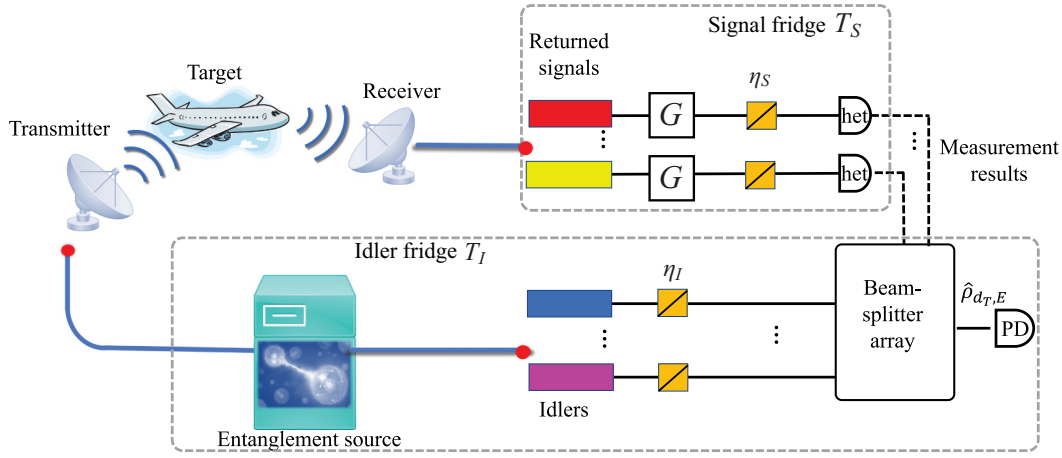

FIG. 1. Schematic of quantum illumination, with a practical receiver based on correlation-to-displacement conversion, in the presence of noise and loss. A set of M signal-idler TMSV states is generated by an entanglement source, with the idler mode (a_I) stored in a refrigerator (at temperature T_I) for later detection. The signal mode (a_S) is transmitted from the transmitter to investigate a target, which is represented by a phase-shift thermal-loss channel ($\Phi_{\kappa,\theta}$). The returning modes (a_R) are gathered at the receiver, where they undergo processing (at temperature T_S). To account for losses (η_S) and noise, they are first amplified (G) before being heterodyne detected (het). The measurement results are then collected and used to operate a programmable beam-splitter array. This array transforms the phase-sensitive cross-correlation among the M signal-idler pairs into the complex displacement amplitude d_T of a collective idler mode (with thermal photon number E) at the output of the array, which is detected by a photodetector (PD). We take into account the impact of imperfect idler detection using the η_I elements, which commute with the beam-splitter array and thus appear beforehand.

(H_1). The asymptotic optimal input state is a two-mode squeezed vacuum (TMSV) state, a bipartite Gaussian state characterized by its covariance matrix (CM) [21,25]

$$\mathbf{V}_{SI} = \begin{pmatrix} (2N_S + 1)\,\mathbf{I} & 2\sqrt{N_S\,(N_S + 1)}\mathbf{Z} \\ 2\sqrt{N_S\,(N_S + 1)}\mathbf{Z} & 2\,(N_S + 1)\,\mathbf{I} \end{pmatrix}, \quad (1)$$

where $\mathbf{Z} = \mathrm{diag}\{1, -1\}$, $\mathbf{I} = \mathrm{diag}\{1, 1\}$, and $\left\langle a_S^\dagger a_S \right\rangle = N_S$ is the signal brightness. While the idler is stored for later detection, the signal is transmitted through a phase-shift thermal-loss channel $\Phi_{\kappa,\theta}$, whose action on its mode when the target is present is described by

$$a_R = e^{i\theta}\sqrt{\kappa}\,a_S + \sqrt{1 - \kappa}\,a_B, \quad (2)$$

while the absence of a target corresponds to the case $\kappa = 0$, i.e., where the channel is $\Phi_{0,0}$. Upon the channel $\Phi_{\kappa,\theta}$, the CM Eq. (1) becomes

$$\mathbf{V}_{RI} = \begin{pmatrix} [2\,(\kappa N_S + N_B) + 1]\,\mathbf{I} & 2\sqrt{\kappa N_S\,(N_S + 1)}\mathbf{R}\mathbf{Z} \\ 2\sqrt{\kappa N_S\,(N_S + 1)}\mathbf{Z}\mathbf{R}^T & (2N_S + 1)\,\mathbf{I} \end{pmatrix}, \quad (3)$$

where $\mathbf{R} = \cos\theta\,\mathbf{I} - i\sin\theta\,\mathbf{Y}$ (with $\mathbf{Y}$ indicating the Pauli-Y matrix) and $\left\langle a_B^\dagger a_B \right\rangle = N_B/\,(1 - \kappa)$ is the mean number of thermal background photons. Table I shows the mean thermal photon number for a typical microwave field at $\omega = 2\pi \times 5$ GHz at temperatures of interest. The signal and return modes propagate at room temperature,

while—depending upon the chosen device—detectors and amplifiers can be operated at temperature T_S equaling either the room temperature, a few kelvins, or ideally close to the Josephson parametric amplifier generating the TMSV state at microwave frequency [26,27], which is typically placed in the cold plate of a dilution refrigerator at about 10 mK [8,19,28]. The idler is always stored in the dilution refrigerator at about $T_I \sim 10$ mK [8,19,28], to enable quantum advantages.

IV. CORRELATION-TO-DISPLACEMENT CONVERSION IN THE IDEAL CASE

Reference [20] proposes a conversion module for capturing and transforming quantum correlation into coherent quadrature displacement, to enable the optimal receiver

TABLE I. Values of mean thermal photon numbers for a microwave mode at $\omega = 2\pi \times 5$ GHz at temperature values of interest.

$\omega/2\pi$ (GHz)	T (K)	$N \sim$
5	3×10^2	1.25×10^3
	10^2	4.15×10^2
	10	40
	4	15
	1	4
	10^{-1}	10^{-1}
	10^{-2}	4×10^{-11}
	4×10^{-3}	9×10^{-27}

design for various entanglement-enhanced protocols. The module is based on heterodyne and programmable passive linear optics, and maps the multimode quantum detection problem to the semiclassical detection problem of a single-mode noisy coherent state, allowing for explicit measurements to achieve the optimal performance. The module provides a paradigm for processing noisy quantum correlations for near-term implementation and can be applied to a wide range of entanglement-enhanced protocols, including quantum illumination, phase estimation, classical communication, target ranging, and thermal-loss channel pattern classification.

QI for target detection considers the discrimination between two channels, $\Phi_{0,0}$ and $\Phi_{\kappa,0}$. In fact, we will consider from now on the simple case of a fixed known phase shift θ (which can always be chosen equal to zero), as the protocol's performance in the large M limit is independent of this phase [6]. Additionally, the possibility of a random return phase shift has been explored [29].

In the ideal case, the conversion module produces the displaced thermal states ρ_{0,N_S} (target absent, H_0) and $\rho_{\sqrt{x},E}$ (target present, H_1), where

$$\rho_{\alpha,E} = \sum_{n=0}^{+\infty} \frac{E^n}{(E+1)^{n+1}} D(\alpha) |n\rangle \langle n| D^\dagger(\alpha), \qquad (4)$$

with $|n\rangle$ a Fock state and $D(\alpha)$ the displacement operator. The total displacement amplitude square $x \sim P^{(M)}(\cdot; \xi_{\text{ideal}})$ obeys a (generalized) χ^2 distribution with $\xi_{\text{ideal}} \equiv \kappa N_S(N_S+1)/2(\kappa N_S + N_B + 1)$. Here the probability density function for the χ^2 distribution parameterized by ξ is given by

$$P^{(M)}(x; \xi) = \frac{x^{M-1}e^{-x/(2\xi)}}{(2\xi)^M \Gamma(M)}, \qquad (5)$$

where $\Gamma(M) = (M-1)!$ is the Γ function [20]. This leads to the error probability performance limit

$$P_{C\to D} = \int_0^{+\infty} dx\, P^{(M)}(x; \xi)\, P_H\left(\rho_{0,N_S}, \rho_{\sqrt{x},E}\right), \qquad (6)$$

where P_H is the Helstrom limit [30–32]

$$P_H(\rho_1, \rho_2) = \frac{1}{2}\left(1 - \frac{1}{2}\text{Tr}\left[|\rho_1 - \rho_2|\right]\right), \qquad (7)$$

in the case of equal prior probability. As shown in Ref. [20], even though the exact solution of Eq. (6) is challenging, we can obtain lower (LB) and upper bounds (UB) for the error exponent $r_{C\to D} = -\lim_{M\to\infty} \ln(P_{C\to D})/M$. The upper bound can be achieved by approximating $\rho_{\sqrt{x},E}$ as a coherent state and ρ_{0,N_S} as vacuum. With respect to the asymptotic analysis, the Helstrom limit

approaches $P_H\left(\rho_{0,N_S}, \rho_{\sqrt{x},E}\right) \sim e^{-x}/4$, which—combined with Eq. (6)—gives the upper bound $r_{C\to D}^{(\text{UB})} = 2\xi$. On the other hand, a lower bound of the conversion module performance can also be obtained as [20]

$$r_{C\to D}^{(\text{LB})} = 2\xi\left(\sqrt{N_S+1} - \sqrt{N_S}\right)^2. \qquad (8)$$

In comparison, the optimal classical case, achieved when a coherent state with mean photon number N_S is sent to the target, has the error exponent

$$r_{\text{CS}} = \kappa N_S\left(\sqrt{N_B+1} - \sqrt{N_B}\right)^2. \qquad (9)$$

In the $N_S \ll 1$ and $N_B \gg 1$ limit, one finds that $r_{C\to D}^{(\text{UB})} \simeq r_{C\to D}^{(\text{LB})} \simeq 4r_{\text{CS}}$, which achieves the optimal advantage.

V. PRACTICAL MICROWAVE DETECTION SCENARIO

Regardless of the technology or setup employed, nonidealities or imperfections will always exist in practical systems, affecting their performance. To mitigate this, we propose the use of a predetection amplifier, which can compensate for additional coupling loss. Our results demonstrate that this approach can effectively improve the performance of binary hypothesis testing and enhance the accuracy of state discrimination.

Before detection, the returned mode is amplified using a quantum amplifier, leading to the amplified mode

$$a_A = \sqrt{G}a_R + \sqrt{G-1}a_V^\dagger, \qquad (10)$$

where $\left\langle a_V^\dagger a_V\right\rangle = N_V$ is the mean photon number of the amplifier noise mode. The amplified a_A and the idler a_I modes share the CM

$$\mathbf{V}_{AI} = \begin{pmatrix} (2N_A+1)\mathbf{I} & V_{12}\mathbf{RZ} \\ V_{12}\mathbf{ZR}^T & (2N_S+1)\mathbf{I} \end{pmatrix}, \qquad (11)$$

where

$$\begin{aligned} N_A &= \left\langle a_A^\dagger a_A\right\rangle \\ &= G[\kappa N_S + N_B + (1 - 1/G)(N_V+1)], \qquad (12) \\ V_{12} &= 2\sqrt{G\kappa N_S(N_S+1)}. \end{aligned}$$

Microwave amplifiers with gain $G \sim 100$ and excess noise of $N_V \sim 10$ photons have been successfully utilized in various microwave QI experiments [19]. Additionally, superconducting quantum computers employ microwave quantum limited amplifiers that exhibit added noise levels
FIG. 2. Behavior of $r_{C\to D}^{(LB)}/r_{CS}$ as a function of $\log_{10}[N_V(1-1/G)]$ with amplification and ideal signal and idler detection, for different values of $\log_{10} N_S$, given $N_B = 1250$ and $\kappa = 0.01$. $N_S = \{10^1, 10^0, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-6}\}$ from bottom to top, as indicated by the labels on top of the curves. The plot indicates that the amplification stage provides a factor of advantage greater than 2 (as indicated by the horizontal dashed line) for a range of relevant parameters. This is due to the robust compensation of noise effects achieved by amplifying, as demonstrated by the vertical dashed line at $N_V(1-1/G) = N_B$.

of about half a photon [33]. The behavior of such experimental systems can be accurately described by the phase-insensitive linear amplifier model presented in Eq. (10).

It should be noted that, comparing Eq. (11) with the one without any amplification Eq. (3), the performance lower bound Eq. (8) applies also to the case with the amplifier, as long as one replaces the parameters $\kappa \to G\kappa$ and $N_B \to N_A - G\kappa N_S$. Furthermore, we see that if $(1 - 1/G)(N_V + 1) \ll N_B$, the performance of the conversion module does not change asymptotically. This is verified in Fig. 2 via calculating $r_{C\to D}^{(LB)}/r_{CS}$ versus $\log_{10}[N_V(1-1/G)]$, where the factor of 4 (6 dB) advantage is seen at the $N_S \ll 1$ limit.

The same analysis can also be applied to the nonideal scenario of imperfect heterodyne detection of the amplified mode and imperfect idler detection. Heterodyne detection efficiency in the microwave regime typically ranges from 40% to 70% depending on the input power. However, in the scope of our analysis, η_S represents the overall channel efficiency, which is dependent on the specific experiment and may be much lower, with realistic values around 10% or even less (down to 1%). Therefore, to account for the efficiencies of the detectors, we introduce two beam splitters, as illustrated in Fig. 1, with transmissivities η_S and η_I, respectively. These beam splitters combine the incoming modes a_A and a_I with their respective thermal modes a_{E_1} and a_{E_2}.

For simplicity, we assume the nonideal heterodyne detection to be symmetric in the quadratures, resulting in

the input-output relation

$$a'_A = \sqrt{\eta_S}a_A + \sqrt{1 - \eta_S}a_{E_1}, \tag{13}$$

where we set $\left\langle a_{E_1}^\dagger a_{E_1} \right\rangle = N_{E_1}$. By performing the analysis through channel composition [see Eqs. (2), (10), and (13)], one can obtain

$$a'_A = e^{i\theta}\sqrt{\eta_S G\kappa}a_S + \sqrt{1 - \eta_S G\kappa}\tilde{a},$$

$$\tilde{a} = \frac{\sqrt{\eta_S G(1-\kappa)}a_B + \sqrt{\eta_S(G-1)}a_V^\dagger + \sqrt{1-\eta_S}a_{E_1}}{\sqrt{1 - \eta_S G\kappa}}, \tag{14}$$

with $[\tilde{a}, \tilde{a}^\dagger] = 1$, and

$$\langle \tilde{a}^\dagger \tilde{a} \rangle = \frac{\eta_S G N_B + \eta_S(G-1)(N_V+1) + (1-\eta_S)N_{E_1}}{1 - \eta_S G\kappa}. \tag{15}$$

With this composition, the channel is now characterized by the parameters

$$\kappa \to \eta_S G\kappa,$$

$$N_B \to \eta_S G\left[N_B + (1-1/G)(N_V+1) + \frac{1-\eta_S}{\eta_S G}N_{E_1}\right]. \tag{16}$$

If we combine this reparameterization with an imperfect idler detection

$$a'_I = \sqrt{\eta_I}a_I + \sqrt{1 - \eta_I}a_{E_2}, \tag{17}$$

with $\left\langle a_{E_2}^\dagger a_{E_2} \right\rangle = N_{E_2}$, the CM of these two nonideal modes a'_A and a'_I can be expressed as

$$\mathbf{V}'_{AI} = \begin{pmatrix} (2N'_A + 1)\mathbf{I} & V'_{12}\mathbf{RZ} \\ V'_{12}\mathbf{ZR}^T & (2N'_I + 1)\mathbf{I} \end{pmatrix}, \tag{18}$$

where we call

$$N'_A = \eta_S G[\kappa N_S + N_B + (1-1/G)$$
$$(N_V+1) + \frac{1-\eta_S}{\eta_S G}N_{E_1}],$$
$$V'_{12} = 2\sqrt{\eta_S \eta_I G\kappa N_S(N_S+1)}, \tag{19}$$
$$N'_I = \eta_I\left(N_S + \frac{1-\eta_I}{\eta_I}N_{E_2}\right).$$

It is worth noting how the dominance of N'_A by N_B in Eq. (19) suggests that excess noise from the electronics may not play a significant role.

VI. CORRELATION-TO-DISPLACEMENT CONVERSION IN PRACTICE

Since the procedure has been extensively discussed in Ref. [20], we will not delve into it in this paper. By heterodyning mode a'_A, one obtains the remaining modes are still in a Gaussian state, resulting in the following expression for the output CM:

$$\mathbf{V}'^{(\text{het})}_{I|A} = \left(2E' + 1\right)\mathbf{I},$$
$$E' = N'_I - \frac{\eta_S \eta_I G\kappa N_S \left(N_S + 1\right)}{N'_A + 1}. \qquad (20)$$

Correspondingly, with measurement result $\overline{\mathbf{x}}_\Pi = (q_\Pi, p_\Pi)^T$, the mean of the nonideal idler becomes

$$\overline{\mathbf{x}}'_I = \frac{\sqrt{\eta_S \eta_I G\kappa N_S \left(N_S + 1\right)}}{N'_A + 1}\left(\begin{array}{c} q_\Pi \cos\theta + p_\Pi \sin\theta \\ q_\Pi \sin\theta - p_\Pi \cos\theta \end{array}\right). \qquad (21)$$

Here Π is just a subscript reminding ourselves that these are measurement outcomes. With the imperfections in consideration, the distribution of the measurement outcomes is given by

$$p\left(\overline{\mathbf{x}}_\Pi\right) = \frac{\exp\left(-\frac{|\overline{\mathbf{x}}_\Pi|^2}{4\left(N'_A + 1\right)}\right)}{4\pi\left(N'_A + 1\right)}, \qquad (22)$$

from which the distribution of $\mathcal{M}_m = \left(q_{\Pi_m} + ip_{\Pi_m}\right)/2$ can be obtained as

$$p\left(\mathcal{M}_m\right) = \frac{\exp\left(-\frac{|\mathcal{M}_m|^2}{N'_A + 1}\right)}{\pi\left(N'_A + 1\right)}. \qquad (23)$$

Finally, by utilizing the displacement conditional on the heterodyne measurement result in the idler complex plane

$$d_m = \frac{\sqrt{\eta_S \eta_I G\kappa N_S \left(N_S + 1\right)}e^{i\theta}\mathcal{M}^\star_m}{N'_A + 1}, \qquad (24)$$

we can express the total displacement of the collective idler mode at the output of the programmable beam-splitter array, through a change of variables, as

$$|d_T|^2 = \sum_{m=1}^{M}|d_m|^2 = \xi\sum_{i=1}^{2M}z_i^2, \quad z_i \sim \mathcal{N}\left(0, 1\right),$$
$$\xi = \frac{\eta_S \eta_I G\kappa N_S \left(N_S + 1\right)}{2\left(N'_A + 1\right)}, \qquad (25)$$

where $\mathcal{N}\left(0, 1\right)$ denotes a Gaussian distribution with zero mean and unit variance. In the following sections, we will make extensive use of the parameter ξ, which plays a critical role in our analysis. We note that $|d_T|^2$ satisfies the χ^2 distribution Eq. (5), with mean $2M\xi$ and variance $4M\xi^2$. Furthermore, Eq. (20) can be conveniently rephrased as $E' = N'_I - 2\xi$.

A. Performance limits of the conversion module in practice

Here we introduce a further, commonly used, benchmark for analyzing the illumination protocol, i.e., the quantum Chernoff bound (QCB). It provides an upper bound for the Helstrom error probability of Sec. IV, which is asymptotically tight in the error exponent for large M [34]. Thus, the error exponent of the QCB provides the best achievable error exponent, and must be larger than $r^{(\text{LB})}_{C\to D}$.

The comparison between the error exponent of the $C \to D$ module [see Eq. (8) and that for the upper bound, which is within the text] and the one obtained from the QCB (see Appendix A for further details) can be seen in Fig. 3, showing that even in the worst-case scenario of lossy amplification and imperfect detection, there is a factor of 2 improvement compared to the classical case Eq. (9). Furthermore, it is worth noting that the lower bound of the conversion module consistently exhibits a close alignment with the QCB. The plots in Fig. 4 provide evidence for the significance of an amplification stage in the microwave domain, where losses from detection may be challenging to overcome. It compares the ratio $r^{(\text{LB})}_{C\to D}/r_{\text{CS}}$ with $r^{(\text{NI})}_{\text{CS}}/r_{\text{CS}}$ versus $\log_{10} G$, in two different temperature conditions (cool and warm). It can be seen that amplification is not necessary in a cool environment, but it is crucial in practical cases characterized by warm environments where $\eta_S < 1/2$: only through amplification can a factor of 2 advantage be achieved, with the emergence of an optimal value of G. In the later part of the paper, we will refer to the parameter setting above as either the "cool case" or the "warm case," referring to the processing temperature of the returned signal.

B. Kennedy receiver

Let us now study the performance of the $C \to D$ module in the case of a specific detection scheme of the conditional idler state. A simple idler's detection scheme is the classical Kennedy receiver, described by the set of POVMs $\Pi_0 = |0\rangle\langle0|$ and $\Pi_1 = \mathbb{1} - \Pi_0$, where $\mathbb{1}$ is the identity operator and $|0\rangle\langle0|$ represents the absence of a photon. The receiver operates in the on-off mode and distinguishes between the presence or absence of a photon.

A practical approach to implement such a receiver is described in Ref. [8], where the authors introduce a method based on a photocurrent and photocounting discriminator. While the calibration and measurement of every parameter in their system are rather complex, the basic idea is to use a dispersive qubit to read out a single photon in a regime
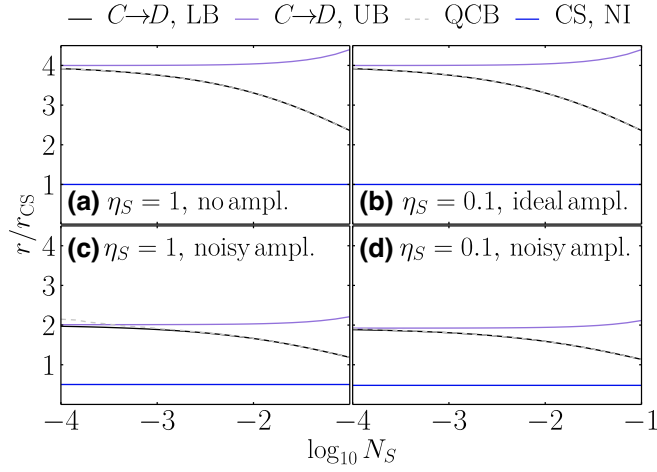

FIG. 3. Black lines represent the ratio $r_{C \to D}^{(LB)}/r_{CS}$ as a function of $\log_{10} N_S$, purple ones $r_{C \to D}^{(UB)}/r_{CS}$, dashed gray for the QCB (see Appendix A), and blue ones $r_{CS}^{(NI)}/r_{CS}$, where r_{CS}^{NI} is obtained by applying the substitution Eq. (16). (a) Ideal return detection, no additional signal loss $\eta_S = 1$ and therefore no amplification needed, $G = 1$. (b) Lossy return detection $\eta_S = 0.1$, assuming pure loss $N_{E_1} = 0$. We apply quantum limited amplification of $G = 100$, $N_V = 0$. (c) Ideal return detection $\eta_S = 1$, and noisy amplification $G = 100$, $N_V = N_B$ at room temperature. (d) Lossy return detection $\eta_S = 0.1$ with noise $N_{E_1} = N_B$ at room temperature. We apply noisy amplification $G = 100$, $N_V = N_B$ at room temperature. The lower bound of the $C \to D$ module consistently aligns with the QCB.

where the probability of having more than one photon is low.

We present a simple approach that provides useful insights and motivates the adoption of a Kennedy receiver, but we will not employ it for our analysis. In the limit where the number of signal photons $N_S \ll 1$ is low, the receiver (neglecting experimental limitations) accurately selects $|0\rangle$ as the measurement outcome. However, the uncertainty in the decision arises from the fluctuations in the coherent state $|\alpha\rangle$. When the equal prior situation $p_0 = p_1 = 1/2$ is considered, the error probability can be calculated as [20]

$$p_e = \frac{1}{2} \langle \alpha| \Pi_1 |\alpha\rangle = \frac{1}{2} e^{-|\alpha|^2} \sim 2P_H \Rightarrow P_K \sim 2P_{C \to D}, \tag{26}$$

when $|\alpha| \gg 1$ [see Eq. (6)].

Nevertheless, the idler photon-counting formula, Eq. (26), considers only the ideal case of vacuum versus coherent state. To account for deviations from this ideal scenario, we introduce a Kennedy receiver that attempts to discriminate between two differently displaced thermal states at finite N_S. In the P representation, the two density

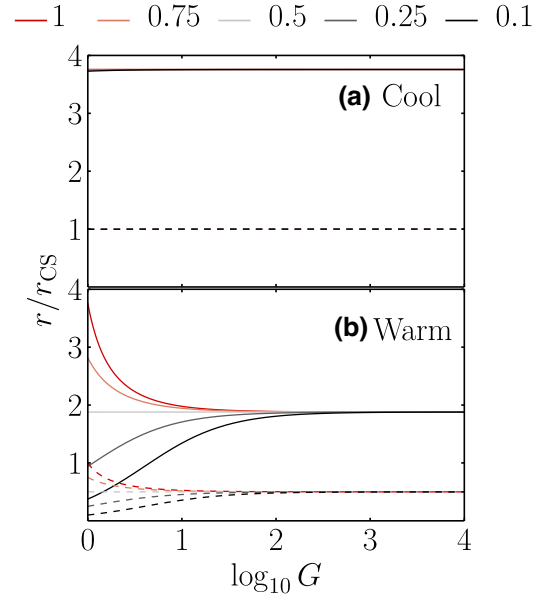

FIG. 4. The impact of losses and gain on two scenarios: (a) a cool case with $N_V = N_{E_1} = 0.1$ (corresponding to $T_S = 100$ mK) and (b) a warm one with $N_V = N_{E_1} = N_B$ (corresponding to $T_S = 300$ K). The other parameters are fixed at $N_B = 1250$, $\kappa = 0.01$, $N_S = 10^{-3}$, and $\eta_I = 1$ (i.e., we assume the idler is ideally stored). Solid lines represent the ratio $r_{C \to D}^{(LB)}/r_{CS}$ as a function of the gain $\log_{10} G$, for different values of η_S (visible in the legend); dashed lines $r_{CS}^{(NI)}/r_{CS}$, where r_{CS}^{NI} is obtained by applying the substitution Eq. (16). Amplification is not necessary in a cool environment (a), but it is crucial in practical cases characterized by warm environments (b) where $\eta_S < 1/2$: only through amplification can a factor of 2 advantage be achieved.

operators to be distinguished are described by [35]

$$\rho_{th}(\delta) = \int_{\mathbb{C}} \frac{d^2\beta}{\pi N_T} \exp\left[-\frac{|\beta - \delta|^2}{N_T} \right] |\beta\rangle\langle\beta|, \tag{27}$$

where $\delta = \{0, \sqrt{x}\}$ is the phase-space displacement, and $N_T = N_I' - \{0, 2\xi\}$ represents the average number of photons produced by thermal noise, with N_I' and ξ defined in Eqs. (19) and (25), respectively. The error probability can then be calculated using the two POVMs as

$$p_e = p_0 \text{Tr}[\Pi_1 \rho_{th}(0)] + p_1 \text{Tr}[\Pi_0 \rho_{th}(\alpha)]$$
$$= p_0 \{\mathbb{1} - \text{Tr}[\Pi_0 \rho_{th}(0)]\} + p_1 \text{Tr}[\Pi_0 \rho_{th}(\alpha)], \tag{28}$$

where $\text{Tr}[\Pi_0 \rho_{th}(\delta)] = \exp\left(-[|\delta|^2/(N_T + 1)]\right)/(N_T + 1)$ [see Eq. (E1) of Ref. [24]]. Applied to our case, the equal prior situation $p_0 = p_1 = 1/2$ yields

$$p_e = \frac{1}{2}\left[1 + \frac{\exp\left(-\frac{x}{N_I' + 1 - 2\xi}\right)}{N_I' + 1 - 2\xi} - \frac{1}{N_I' + 1} \right]. \tag{29}$$

Finally, the error probability of the Kennedy receiver is given by

$$P_K = \int_0^{+\infty} dx \, P^{(M)}(x;\xi) \, p_e, \tag{30}$$

with $P^{(M)}(x;\xi)$ given in Eq. (5). In other words,

$$P_K = \frac{1}{2(N_I'+1)}\left[\left(1+\frac{2\xi}{N_I'+1-2\xi}\right)^{1-M} + N_I'\right]. \tag{31}$$

While we have adopted the Kennedy receiver in this work, it is worth noting that further performance improvements can be achieved by optimizing the displacement amplitude and consider the improved Kennedy receiver [36].

VII. PERFORMANCE BENCHMARKS

In order to assess the performance of the $C \to D$ module, we compare it with a classical benchmark based on coherent states and homodyne detection. The error probability of homodyne detection is given by [2]

$$P_{E,\text{homo}} = \frac{1}{2}\,\text{erfc}\left[\sqrt{\frac{\kappa M N_S}{2(2N_B+1)}}\right], \tag{32}$$

where $\text{erfc}[z] = (2/\sqrt{\pi})\int_z^{+\infty} dt\, e^{-t^2}$ is the complementary error function.

Besides the classical scheme, we also benchmark with known practical receivers for QI such as the PCR scheme [16,20], whose error probability in the QI scenario is simply given by (details can be found in Appendix B)

$$P_{E,\text{PCR}} = \frac{1}{2}\,\text{erfc}\left(\sqrt{R_{\text{PCR}}M}\right),$$

$$R_{\text{PCR}} = \frac{\mu_1^2}{4}\left[2N_I' + (G_{\text{PCR}}-1)(2N_I'+1)\right.$$

$$\times (N_A' + N_{A,\kappa=0}' + 2)$$

$$\left. + \mu_1^2/2 + 2G_{\text{PCR}}N_{V_{\text{PCR}}}\right]^{-1}, \tag{33}$$

where μ_1 is given by Eq. (B8), and G_{PCR} and $N_{V_{\text{PCR}}}$ correspond to the gain and mean number of added photons of the phase conjugator, respectively. Figure 5 shows a comparison between the performance limits of the $C \to D$ module and PCR in terms of error exponents [see Eqs. (8) and (33), respectively]. Although we present only the performance analysis for the cool case of return signal processing, it is noteworthy that the $C \to D$ module exhibits superior performance compared to the PCR, as evidenced by a significantly larger region of parameter space with better performance, as indicated by the yellow coloration. The

FIG. 5. Comparison of the error exponent ratio r/r_{CS} between the $C \to D$ module and the PCR [see Eqs. (8), (33), and (9), respectively] as a function of $\log_{10} N_S$ and $\log_{10} N_B$. The other parameters correspond to the "cool" case and are set to $N_V = N_{E_1} = N_{V_{\text{PCR}}} = 0.1$ (corresponding to $T_S = 100$ mK), $N_{E_2} = 4 \times 10^{-11}$ (corresponding to $T_I = 10$ mK), $G = 100$, $G_{\text{PCR}} = 2$, $\eta_S = 0.1$, and $\eta_I = 0.9$. The red circle represents the parameters used in Fig. 6. The $C \to D$ module possesses clear better performance, as stated by the wide yellowish areas.

scaling of major error probabilities with the number of copies M is shown in Fig. 6, for both the warm and cool cases. Note that the parameter setting of Fig. 6 corresponds to the red dot in Fig. 5. Specifically, we focus on the performance of the $C \to D$ module with Kennedy receiver (red lines), which is almost comparable to that of the QCB (blue) and outperforms any other practical scheme considered. The saturation of the $C \to D$ performance is due to the on-off detection of Kennedy receiver, as we will resolve in Sec. VIII. We also present the comparison to the Nair-Gu lower bound [21] (light gray), which shows similar scaling of the QCB. In Fig. 5, the dashed curves are the performance curves of the receivers assuming all equipment become ideal, instead the solid curves where imperfections are considered (the same color coding of the curves are adopted for both dashed and solid, as indicated by the legend). To provide a comparison between the $C \to D$ module equipped with an on-off Kennedy receiver and the PCR, Fig. 7 presents the error probability ratio $\log_{10}(P_E/P_{E,\text{homo}})$ for the cool case, where M is chosen such that the homodyne error probability is fixed at $P_{E,\text{homo}} = 0.05$. As shown by the wide dark area, the $C \to D$ module clearly outperforms the PCR in the $N_B \gg 1$, $N_S \ll 1$ parameter regime.

VIII. ENHANCED PERFORMANCE WITH NUMBER-RESOLVING DETECTION

So far we have adopted the Kennedy receiver with on-off detection, which leads to the saturation of error probability (red lines) in Fig. 6 at large M. To obtain better performance, in this section we generalize the Kennedy
FIG. 6. Error probability as a function of the number of copies M in both the nonideal (solid) and ideal (dashed) case. The nonideal case is characterized by $N_S = 10^{-3}$, $N_B = 1250$, $N_{E_2} = 4 \times 10^{-11}$ (corresponding to $T_I = 10$ mK), $\kappa = 0.01$, $G = 100$, $\eta_S = 0.1$, $\eta_I = 0.9$, and $G_{\mathrm{PCR}} = 2$. (a) Cool case with $N_V = N_{E_1} = N_{V_{\mathrm{PCR}}} = 10^{-1}$ (corresponding to $T_S = 100$ mK), (b) warm one $N_V = N_{E_1} = N_{V_{\mathrm{PCR}}} = 1250$ (corresponding to $T_S = 300$ K). Dashed lines are the performance for each solid colored curve in the ideal scenario ($\eta_S = \eta_I = 1$ and no amplification $G = 1$). The horizontal dashed line marks $P_{E,\mathrm{homo}} = 0.05$.

FIG. 7. Comparison based on the error probability ratio $\log_{10}\left(P_E/P_{E,\mathrm{homo}}\right)$ between (a) the $C \to D$ module (equipped with an on-off Kennedy receiver) and (b) the PCR [see Eqs. (31), (33), and (32), respectively] versus $\log_{10} N_S$ and $\log_{10} N_B$. The value of M is selected to set $P_{E,\mathrm{homo}} = 0.05$. The other parameters correspond to the "cool" case and are $N_V = N_{E_1} = N_{V_{\mathrm{PCR}}} = 0.1$, $N_{E_2} = 4 \times 10^{-11}$, $G = 100$, $G_{\mathrm{PCR}} = 2$, $\eta_S = 0.1$, and $\eta_I = 0.9$. The red circle indicates the parameters used in Fig. 6. As shown by the wide dark area, the $C \to D$ module outperforms the PCR.

receiver to a photon-number-resolving detector (PNRD) on the idler.

As already analyzed, the decision between the presence or absence of the target is equivalent to discriminating between two states of the final idler mode after the beam-splitter array: the thermal state $\rho_{0,N_I'}$ when the target is absent, and the displaced thermal state $\rho_{\sqrt{x},E'}$ when it is present. Recall that N_I' is defined by Eq. (19), E' by Eq. (20), and x is a random variable associated with the results of M heterodyne measurements on the return modes, distributed according to Eq. (5), with ξ given by Eq. (25). With a PNRD detection, we can now compare the photon-number probability distributions for the two hypotheses: $p_n^{(0)} = \langle n| \rho_{0,N_I'} |n\rangle$ and $p_n^{(1)}(x) = \langle n| \rho_{\sqrt{x},E'} |n\rangle$. The presence of the target is declared when the outcome of the photon-number measurement is greater than a predetermined threshold value, $n \geq n_D \geq 1$.

To prepare our analyses for the ROC curve, we consider the false alarm probability P_F and the detection probability
P_D for a fixed decision threshold n_D as

$$P_F = \sum_{n=n_D}^{+\infty} \langle n| \rho_{0,N_I'} |n\rangle, \tag{34}$$

$$P_D = \sum_{n=n_D}^{+\infty} \int_0^{+\infty} dx\, P^{(M)}(x;\xi) \langle n| \rho_{\sqrt{x},E'} |n\rangle, \tag{35}$$

where we average over the random variable x.

The evaluation of P_F is simple and one has

$$P_F(n_D) = \left(\frac{N_I'}{N_I' + 1}\right)^{n_D}, \tag{36}$$

while that of P_D is more involved. We start by using the following result for the photon statistics of a displaced thermal state for a given x [37,38]:

$$p_n^{(1)}(x) = \frac{\exp\left(-\frac{x}{E'+1}\right)}{E'+1}\left(\frac{E'}{E'+1}\right)^n L_n\left[-\frac{x}{E'(E'+1)}\right], \tag{37}$$

where $L_n[\cdot]$ is the nth Laguerre polynomial. Next, one can perform the average over the probability distribution Eq. (5) to obtain the average photon-number probability

distribution when the target is present

$$\bar{p}_n^{(1)}(M;\xi) = \frac{(E'+1)^{M-n-1}E'^n}{(E'+1+2\xi)^M} \, {}_2F_1$$

$$\times \left[M, -n, 1, -\frac{2\xi}{E'(E'+1+2\xi)} \right], \quad (38)$$

where ${}_2F_1(a,b,c,z)$ is the Gaussian hypergeometric function. Consequently, the detection probability $P_D(n_D)$ can be exactly determined as

$$P_D(n_D) = 1 - \sum_{n=0}^{n_D-1} \bar{p}_n^{(1)}(M;\xi). \quad (39)$$

A. Bayesian error probability

To begin with, we consider the symmetric error $P_E = (P_F + 1 - P_D)/2$ and evaluate the performance. Here the results are similar to that of Ref. [29]. This is because, given the choice of photon counting, random phase does not change the performance anymore. From Eqs. (38) and (36), we have the error probability P_E as a function of the threshold n_D. We compare this optimal decision strategy with a variable threshold n_D, and quantify the error of probability using

$$P_{C \to D}^{(n_D)} = \frac{1}{2} \left[1 - \sum_{n=0}^{n_D-1} \gamma_n(2M;\xi) \right], \quad (40)$$

where the function

$$\gamma_n(M;\xi) = \frac{N_I'^n}{\left(N_I'+1\right)^{n+1}} - \frac{(E'+1)^{M-n-1}E'^n}{(E'+1+2\xi)^M} \, {}_2F_1$$

$$\times \left[M, -n, 1, -\frac{2\xi}{E'(E'+1+2\xi)} \right]. \quad (41)$$

Although the above equation is exact, to enable efficient numerical evaluation in all parameter regions of interest, we further make an approximation at the $M \gg 1$ limit and obtain

$$\gamma_n(M;\xi) \simeq \frac{N_I'^n}{\left(N_I'+1\right)^{n+1}} - \frac{E'^n}{(E'+1)^{n+1}} e^{-2M\xi/E'} \, {}_1F_1$$

$$\times \left[n+1, 1, \frac{2M\xi}{E'(E'+1)} \right]. \quad (42)$$

The precision of such an approximation is sufficient for our evaluation, as verified in Ref. [29]. The optimal performance is then given by a minimization of the error probability over the threshold n_D,

$$P_{C \to D}^{(\text{opt})} = \min_{n_D \geq 1} P_{C \to D}^{(n_D)}. \quad (43)$$

Note that $P_{C \to D}^{(1)} \equiv P_K$ [see Eq. (31)], as expected.

FIG. 8. The saturation of the red line in Fig. 6 suggests an improvement, following the lines of Ref. [29], where a variable threshold decision strategy approach has been used for asymptotic analysis. The red curve reproduces the usual Kennedy receiver corresponding to the fixed threshold $n_D = 1$. The dashed gray lines correspond to the case of fixed, increasing values of n_D. The orange line gives the optimized result in which n_D is adjusted according to M, and therefore to the two states to be discriminated. This latter approach yields results comparable to those of the nonideal QCB (blue). Parameter values are the same as those of Fig. 6.

Figure 8 shows the results of our analysis, using the same parameter values as in Fig. 6. We observe that the optimized approach (orange) produces results that are comparable to those of the nonideal QCB (blue, see also Appendix A). Specifically, the irregular trend in the data is well described by a variable threshold decision strategy approach, which is represented by the dashed lines in the figure. Our findings suggest that the optimized approach can effectively discriminate between the two states of interest, even in the presence of noise and other imperfections.

B. Receiver operating characteristic

1. Conversion module and photon-number-resolving detector

Let us now analyze the performance of the $C \to D$ module within the Neyman-Pearson framework, which is suitable in some radar operations [39], using ROC curves. In this approach, a chosen false alarm probability P_F is fixed, and the goal is to maximize the detection probability P_D. By gradually reducing the threshold value n_D

from a high (ideally infinite) value to zero, a concave ROC curve can be obtained, plotting P_D versus P_F, starting from $P_F = P_D = 0$ and ending at $P_F = P_D = 1$.

To gain a clearer understanding of the behavior of the ROC curve, we derive an analytical expression based on a Gaussian approximation. When $x \gg 1$, the probability distribution $p_n^{(1)}(x)$ Eq. (37) can be represented by a Gaussian distribution with mean $\langle n(x) \rangle = E' + x$, and variance $\sigma_n^2(x) = \langle n^2(x) \rangle - \langle n(x) \rangle^2 = E'^2 + E' + x(2E' + 1)$. As a result, in this limit, the average probability distribution Eq. (38) can also be approximated by a Gaussian distribution with properly averaged mean and variance, and we have

$$\bar{p}_n^{(1)}(M;\xi) \sim \frac{1}{\sqrt{2\pi\sigma_n^2}} \exp\left[-\frac{(n-\bar{n})^2}{2\sigma_n^2}\right], \quad (44)$$

with

$$\bar{n} = E' + \bar{x}$$
$$= E' + 2M\xi, \quad (45)$$

$$\sigma_n^2 = E'^2 + E' + \bar{x}(2E' + 1) + \sigma_x^2$$
$$= E'^2 + E' + 2M\xi(2\xi + 2E' + 1), \quad (46)$$

taking into account that the distribution Eq. (5) has mean $\bar{x} = 2M\xi$, and variance $\sigma_x^2 = 4M\xi^2$. A necessary condition for the validity of such a Gaussian treatment is that $\bar{x} = 2M\xi \gg 1$. By using the Gaussian approximation Eq. (44), and eliminating the threshold n_D with the aid of Eq. (36), one gets the following approximate expression for the ROC curve of the $C \to D$ module

$$P_D(P_F) \sim \frac{1}{2}\,\text{erfc}\left[\frac{1}{\sigma_n\sqrt{2}}\left(\frac{\log P_F}{\log\left(\frac{N_I'}{N_I'+1}\right)} - \bar{n}\right)\right]. \quad (47)$$

This approximation provides a satisfactory description of the ROC curves for moderate values of P_D and P_F as long as $2M\xi > 1$. Although the average probability distribution $\bar{p}_n^{(1)}(M;\xi)$ resembles a Gaussian distribution around the peak centered at its average value, it decays exponentially, not Gaussianly, for $P_F \to 0 \Rightarrow P_D \to 0$, i.e., $n_D \to \infty$. As a result, Eq. (47) tends to underestimate the value of P_D for high threshold values n_D.

2. The ROC curve in the case of the PCR

As discussed in Appendix B (see also Ref. [40]), when $M \gg 1$, the photocount difference of the PCR, $N = N_+ - N_-$, according to the central limit theorem, follows a Gaussian distribution with a probability density for the two

hypotheses

$$P_{N|H_{0/1}}\left(n|H_{0/1}\right) = \frac{\exp\left[-\frac{(n-M\mu_{0/1})^2}{2M\sigma_{0/1}^2}\right]}{\sqrt{2\pi M\sigma_{0/1}^2}}, \quad (48)$$

where the two mean values $\mu_{0/1}$ and the two variances $\sigma_{0/1}^2$ are given by Eq. (B8).

The discrimination between two Gaussian distributions with different means and variances can be obtained by using the extended van Trees approximation [41], and it can be expressed in terms of the auxiliary function

$$\mu(s) = \ln\left\{\frac{\sigma_1^{1-s}\sigma_0^s}{\sqrt{s\sigma_0^2 + (1-s)\sigma_1^2}}\right.$$
$$\left.\times \exp\left\{-\frac{M(\mu_0 - \mu_1)^2 s(1-s)}{2\left[s\sigma_0^2 + (1-s)\sigma_1^2\right]}\right\}\right\}, \quad (49)$$

where s is a threshold parameter. The false alarm and detection probabilities are then, respectively, given by

$$P_F = \frac{1}{2}\text{erfc}\left[s\sqrt{\frac{\ddot{\mu}(s)}{2}}\right],$$
$$P_D = 1 - \frac{1}{2}\text{erfc}\left[(1-s)\sqrt{\frac{\ddot{\mu}(s)}{2}}\right], \quad (50)$$

where $\ddot{\mu}(s) \equiv d^2\mu/ds^2$.

However, one can get a simpler and clearer expression by taking into consideration that the variances for the two hypothesis, σ_0^2 and σ_1^2, are nearly identical for the typical parameter values in a microwave QI experiment, that is, when $\kappa \ll 1$, $N_S \ll 1$, and $N_B \gg 1$. In fact, Eq. (B8) gives

$$\frac{\sigma_1^2 - \sigma_0^2}{\sigma_0^2} = \eta_S G\left(G_{\text{PCR}} - 1\right)\kappa N_S\left[2N_I' + 1 + 2\eta_I(N_S + 1)\right]$$
$$\times \left[N_I' + (G_{\text{PCR}} - 1)\left(2N_I' + 1\right)\left(N_{A,\kappa=0}' + 1\right)\right.$$
$$\left. + G_{\text{PCR}}N_{V_{\text{PCR}}}\right]^{-1}, \quad (51)$$

which scales as $\kappa N_S/N_B \ll 1$ when $N_B \gg N_S$. As a result, one has $\ddot{\mu}(s) = M\mu_1^2/\sigma_1^2 \equiv d_{\text{PCR}}^2$ in Eqs. (50), which can be rewritten as

$$P_F = \frac{1}{2}\text{erfc}\left[\frac{1}{\sqrt{2}}\left(\frac{\ln\eta}{d_{\text{PCR}}} + \frac{d_{\text{PCR}}}{2}\right)\right],$$
$$P_D = \frac{1}{2}\text{erfc}\left[\frac{1}{\sqrt{2}}\left(\frac{\ln\eta}{d_{PCR}} - \frac{d_{\text{PCR}}}{2}\right)\right], \quad (52)$$

where we introduce the alternative threshold parametrization as $\ln\eta = (s - 1/2)d_{\text{PCR}}^2$. By eliminating this threshold parameter, the analytical expression of the ROC curve
FIG. 9. Comparison of ROC curves. The red line shows the performance of the $C \to D$ module with a PNRD; the black one that of the PCR given by Eq. (53); the dashed light gray line depicts the performance of the Gaussian approximation of Eq. (47); the full dark grey line gives the nonideal classical benchmark [using Eq. (53) with $d_{\text{PCR}} \to d_{\text{CS}}$ plus Eq. (16)]. The parameters used are the same as in Fig. 5 and 7 (indicated by the red dots there), with $M = 69 \times 10^7$.

for the PCR can be obtained as

$$P_D = \frac{1}{2}\text{erfc}\left[\text{erfc}^{-1}(2P_F) - \frac{d_{\text{PCR}}}{\sqrt{2}}\right], \quad (53)$$

where $\text{erfc}^{-1}(z)$ is the inverse of the complementary error function. We notice that the ROC curve for the PCR is analytically identical to that of the optimal classical benchmark of using coherent states and homodyne detection. Both have the same form as in Eq. (53), but the replacement $d_{\text{PCR}} \to d_{\text{CS}} = 2\sqrt{M\kappa N_S/(2N_B + 1)}$ [40].

Figure 9 presents the behavior of the ROC curve for the $C \to D$ module in both warm and cool cases, considering losses and amplification in the detection scheme. The results are compared to the corresponding Gaussian approximation Eq. (47), the PCR Eq. (53), and the nonideal classical benchmark [using Eq. (53) with $d_{\text{PCR}} \to d_{\text{CS}}$ and Eq. (16)], all obtained under the same experimental conditions.

When the Neyman-Pearson decision strategy is considered, it can be observed that the $C \to D$ module exhibits excellent performance in both the cool and warm cases. In particular, its ROC curve is significantly larger than those

obtained with the PCR and the classical approach for the same experimental conditions.

IX. CONCLUSIONS

In conclusion, this work analyzed how experimental imperfections can be mitigated using correlation-to-displacement conversion-based receivers, and our results showed that amplification on the return signals can effectively compensate for additional loss in the heterodyne detection. We also employed a Kennedy receiver for idler detection conditioned on heterodyne and demonstrated that in the ideal case, such a scheme has the optimal error exponent. In practical scenarios, such a receiver still provides quantum advantages over classical optimal schemes and outperforms other known practical receivers for quantum illumination.

Compared to suboptimal receivers like OPA and PCR, the receiver design proposed in Ref. [20] and further developed here, based on $C \to D$ conversion, not only achieves optimality but also eliminates the need for direct interaction between the idlers and the returns. This is particularly advantageous for microwave quantum illumination, where idlers require low-temperature cooling and isolation, while the returns are noisy and at room temperature. By relying only on heterodyne and photon detection, this receiver design significantly reduces the technical challenges associated with optimal receivers, as compared to previous proposals based on sum-frequency generation [17].

Recent attention has focused on exploring non-Gaussian states as quantum probes in QI [42,43]. However, it is established that TMSV states are asymptotic optimal for QI with a given signal-photon number [21,25,44]: Reference [25] proved the optimality for asymmetric hypothesis testing, while Refs. [21,44] find TMSV to be optimal in the symmetric hypothesis testing in the weak reflectivity and large noise limit. The $C \to D$ conversion scheme described in this study could also be extended to the non-Gaussian scenario. Although the analysis may be more complex, our findings indicate that comparable asymptotic performance can potentially be achieved.

Overall, our findings illustrate the feasibility of practical microwave quantum illumination systems that can overcome experimental imperfections and offer quantum advantages for target detection in noisy environments. These insights can inform the development of future quantum illumination systems and contribute to the advancement of quantum sensing technologies.

APPENDIX A: QUANTUM CHERNOFF BOUND

The quantum Chernoff bound (QCB) is a powerful tool for determining an upper bound to the Helstrom limit P_H [45–48]. It is particularly useful for an ensemble of Gaussian states $\{\rho_h\}$, where it can be efficiently computed using symplectic decomposition. In our specific case of discriminating between $\Phi_{0,0}$ and $\Phi_{\kappa,0}$, this corresponds to the discrimination of $\{\rho_h\}_{h=0}^\kappa$, with mean $\overline{x}_h = 0$ and CM $V'^{(h)}_{AI}$ [see Eq. (18) with $\theta = 0$]. Indeed, the matrix $V'^{(h)}_{AI}$ can be denoted as

$$V'^{(h)}_{AI} = \begin{pmatrix} a_h \mathbf{I} & c_h \mathbf{Z} \\ c_h \mathbf{Z} & b \mathbf{I}, \end{pmatrix}, \qquad (A1)$$

with $a_h = 2N'_A + 1$, $b = 2N'_I + 1$, and $c_h = V'_{12}$. Its symplectic eigenspectrum is then given by

$$\nu^{(h)}_\pm = \frac{\sqrt{y_h} \pm (b - a_h)}{2}, \qquad (A2)$$

where $y_h = (a_h + b)^2 - 4c_h^2$, and with the symplectic matrix $\mathbf{S}_h$ described by

$$\mathbf{S}_h = \begin{pmatrix} \omega^{(h)}_+ \mathbf{I} & \omega^{(h)}_- \mathbf{Z} \\ \omega^{(h)}_- \mathbf{Z} & \omega^{(h)}_+ \mathbf{I}, \end{pmatrix}, \quad \omega^{(h)}_\pm = \sqrt{\frac{a_h + b \pm \sqrt{y_h}}{2\sqrt{y_h}}}. \qquad (A3)$$

In this regard, the QCB is simply expressed as

$$P_{\mathrm{QCB}} = \frac{1}{2} \left(\inf_{s \in [0,1]} \overline{Q}_s \right)^M, \qquad (A4)$$

where $\overline{Q}_s = 4\det(\mathbf{\Sigma}_s)^{-1/2} \prod_{j=1}^2 G_s\left(\nu^{(0)}_j\right) G_{1-s}\left(\nu^{(\kappa)}_j\right)$, $\mathbf{\Sigma}_s = \widetilde{\mathbf{V}}_0(s) + \widetilde{\mathbf{V}}_\kappa(1 - s)$, and having defined

$$\widetilde{\mathbf{V}}_h(s) = \mathbf{S}_h \left[\bigoplus_{j=1}^2 \Lambda_s\left(\nu^{(h)}_j\right) \mathbf{I} \right] \mathbf{S}_h^T,$$

$$G_s(x) = \frac{2^s}{(x+1)^s - (x-1)^s}, \qquad (A5)$$

$$\Lambda_s(x) = \frac{(x+1)^s + (x-1)^s}{(x+1)^s - (x-1)^s}.$$

APPENDIX B: PHASE-CONJUGATE RECEIVER

To ensure clarity and avoid confusion for the reader, we reintroduce the hat notation in this section, to distinguish between an operator $\hat{O}$ and its corresponding mean value $O = \langle \hat{O} \rangle$.

In a PCR the $\hat{a}'_A$ modes are phase conjugated according to the following transformation:

$$\hat{a}_C = \sqrt{G_{\mathrm{PCR}}} \hat{a}_{V_{\mathrm{PCR}}} + \sqrt{G_{\mathrm{PCR}} - 1} \hat{a}'^\dagger_A, \qquad (B1)$$

where G_{PCR} is the gain and $\hat{a}_{V_{\mathrm{PCR}}}$ is the annihilation operator of the noise entering the unused port of the PCR. The conjugated modes are then recombined on a balanced beam splitter with the nonideal idler mode $\hat{a}'_I$ as $\hat{a}_\pm = \left(\hat{a}_C \pm \hat{a}'_I \right) / \sqrt{2}$, that is

$$\hat{a}_\pm = \frac{1}{\sqrt{2}} \left(\sqrt{G_{\mathrm{PCR}}} \hat{a}_{V_{\mathrm{PCR}}} + \sqrt{G_{\mathrm{PCR}} - 1} \hat{a}'^\dagger_A \pm \hat{a}'_I \right). \quad (B2)$$

In the following analysis, we will not consider terms whose mean value $\langle \cdot \rangle$ is null, such as those linear in $\hat{a}_{V_{\mathrm{PCR}}}$. Similarly, we will group together terms whose mean value $\langle \cdot \rangle$ is equal, that is, $\langle \hat{a}'_A \hat{a}'_I \rangle = \langle \hat{a}'^\dagger_I \hat{a}'^\dagger_A \rangle$. That said, the photon numbers at the output of the beam splitter can be expressed as

$$\hat{N}_\pm = \hat{a}^\dagger_\pm \hat{a}_\pm$$
$$= \frac{1}{2} \left[\hat{N}_C \pm 2\sqrt{G_{\mathrm{PCR}} - 1} \hat{a}'_A \hat{a}'_I + \hat{N}'_I \right], \qquad (B3)$$

where

$$\hat{N}_C = \hat{a}^\dagger_C \hat{a}_C$$
$$= G_{\mathrm{PCR}} \hat{N}_{V_{\mathrm{PCR}}} + (G_{\mathrm{PCR}} - 1) \left(\hat{N}'_A + 1 \right), \quad (B4)$$
$$\hat{N}_{V_{\mathrm{PCR}}} = \hat{a}^\dagger_{V_{\mathrm{PCR}}} \hat{a}_{V_{\mathrm{PCR}}}.$$

When $M \gg 1$, the photo-count difference $N = N_+ - N_-$, according to the central limit theorem, follows a Gaussian distribution with mean $M\mu$, where

$$\mu = \sqrt{G_{\mathrm{PCR}} - 1} V'_{12}, \qquad (B5)$$

and variance $M\sigma^2$, with

$$\sigma^2 = N_+ (N_+ + 1) + N_- (N_- + 1) - (N_C - N'_I)^2 / 2$$
$$= G_{\mathrm{PCR}} N_{V_{\mathrm{PCR}}} + (G_{\mathrm{PCR}} - 1)(N'_A + 1) + N'_I$$
$$+ 2(G_{\mathrm{PCR}} - 1)(N'_A + 1) N'_I + (G_{\mathrm{PCR}} - 1) V'^2_{12} / 2. \qquad (B6)$$

The values of the mean μ and the variance σ^2 are influenced by both the off-diagonal CM element V'_{12} and N'_A,

which vary depending on whether the target is present (H_1) or absent (H_0). Using the Gaussian approximation, in the QI scenario, the error probability is simply given by

$$P_{E,\text{PCR}} = \frac{1}{2} \operatorname{erfc}\left(\sqrt{R_{\text{PCR}}M}\right), \quad R_{\text{PCR}} = \frac{(\mu_1 - \mu_0)^2}{4\left(\sigma_1^2 + \sigma_0^2\right)}, \tag{B7}$$

where the mean and variance for the two hypotheses are given by

$$\begin{aligned}
\mu_0 &= 0, \\
\mu_1 &= 2\sqrt{\eta_S \eta_I G \left(G_{\text{PCR}} - 1\right) \kappa N_S \left(N_S + 1\right)}, \\
\sigma_0^2 &= N_I' + \left(G_{\text{PCR}} - 1\right)\left(2N_I' + 1\right)\left(N_{A,\kappa=0}' + 1\right) \\
&\quad + G_{\text{PCR}} N_{V_{\text{PCR}}}, \\
\sigma_1^2 &= N_I' + \left(G_{\text{PCR}} - 1\right)\left(2N_I' + 1\right)\left(N_A' + 1\right) \\
&\quad + G_{\text{PCR}} N_{V_{\text{PCR}}} + \mu_1^2/2, \tag{B8}
\end{aligned}$$

resulting in the expression given for R_{PCR} in the main text.
